I. INTRODUCTION TO THE EXPERIMENT

A. Goals of the experiments

The basic goals of these experiments are to help familiarize us with the fourth state of matter: plasma, and to get to know a simple way of creating laboratory plasma for research purpose (a cartoon of which is shown in figure 1). Further, we want to understand how Langmuir probes work. The Langmuir probe (see references 1 & 2 in the background readings section), is the one the most versatile diagnostic for plasma physics research. The student will learn how to interpret the data gathered by Langmuir probes in order to determine plasma parameters such as plasma density ($n_e$), temperature ($kT_e$), and how these parameters depend on the discharge parameters of a magnetically confined thermionic discharge plasma (figure 2). The description of these experiments is followed by a brief introduction to the plasma state of matter itself in section II, followed by more references. Among those references you’ll find a paper very pertinent to these experiments, which have been done before in similar devices\(^1\). The student is aware at this point in the semester of how useful it is to look at previous results wherever this is possible. Finally, parameters measured with Langmuir probes will be used to make theoretical predictions regarding ion acoustic waves. The phase velocity of ion acoustic waves may be measured directly using the tone-burst technique (see ref. 5 in the background reading sections and described briefly below) depend on the electron temperature, and the model we use to assess the phase velocity, the dispersion relationship, permits us to predict the speed of the waves, and so to compare theory with experiment. This is essentially the point of these experiments.

B. Procedure

Plasmas can be created when energetic particles meet neutral atoms and molecules, causing ionization, and when sufficiently high plasma density results. In the plasma physics experiments conducted here at USD, the plasma is created by accelerating thermionically emitted electrons from hot filaments ($T_f > 2400\text{K}$) biased to a negative potential (the so-called discharge current) with respect to the vacuum chamber wall, as shown in figure 2. When the discharge voltage significantly exceeds the ionization potential of the feed gas (argon, in our case), the energetic electrons (called ‘primary electrons’), may create an ion, electron pair, in an ionization collision,

$$e_p + Ar \rightarrow Ar^+ e + e_p,$$

where the subscript denotes the primary electron, which must loose energy at the expense of the ionization potential of the neutral (and any internal energy imparted to the ion), and where ion-electron pair primarily compose the plasma. Of course, the entire collection of ions, electrons, and neutrals compose the plasma, and the col-

FIG. 1. Not just any collection of charged particles, with roughly equal concentrations of positive and negative charges, exhibit collective behavior distinctive of the plasma state of matter. The electron and ion densities have to be great enough and these populations have to be hot enough for ‘medium like’ behavior to become important. Plasma crowns our planet, above and below (the aurora), surrounds it (ionosphere, magnetosphere), and heats it (the sun and all stars are in the plasma state, and most are made of classical plasma)
Measure the $I - V$ (current-voltage) characteristic for a planar Langmuir probe (see references 1 & 2 cited above, and a worksheet will be provided to help with this) in a steady state discharge, using a simple probe-bias sweep circuit. Mark the plasma space potential, $V_s$, the floating potential, $V_f$, electron saturation current, $I_{es}$, and ion saturation current, $I_{is}$. Subtract $I_{es}$ from $I(V)$, and so plot the electron current on log-linear (semi-log) axes.

Determine the electron temperature, $T_e$, and the electron plasma density, $n_e$. Note the discharge parameters, $I_{dis}$, $V_{dis}$, and $p_o$, and the probe area. In your lab notebook, tape in a hardcopy of a good $I - V$ characteristic, and a semi-log plot of the electron branch of the $I - V$ characteristic, marking the location of the plasma potential and the floating potential, and demonstrate the calculation of $n_e$ and $T_e$.

Obtain $I - V$ characteristics at different discharge currents (500 $mA < I_{dis} < 1,500$ $mA$) and fixed discharge voltage and neutral pressure, ($V_{dis} = 80$ $V$, say, and $p_o5 \times 10^{-4}$torr), and do the same for different neutral pressures ($1 \times 10^{-5} < p_o < 8 \times 10^{-4}$torr) for fixed discharge voltage and discharge current (say, 60$V$ and 1amp, respectively). Evaluate the results and show how the plasma density, temperature, and potential depend on the discharge current, and neutral pressure. Plot the data and tape the hardcopy into your notebook, and try to account for the curves qualitatively. Calculate the fractional ionization of the plasma as a function of neutral pressure. Does the result surprise you? In your paper, you’ll want to capture the essence of the parameter studies and try to interpret the trends in the graphs. The background reference help a great deal here, especially MacKenzie’s paper.

C. Part II: collective effects—ion acoustic waves

The plasma state of matter supports a variety of collective effects one of which is longitudinal ($k \parallel \mathbf{E}$), electrostatic ($\mathbf{B} = 0$) waves. These low frequency waves follow as the result of introducing a perturbation of the ion density which thereafter propagates in the medium (the plasma). Your mission is to introduce such a perturbation into the plasma and then to measure the speed of propagation. These waves are weird. They are analogous to sound waves in air, but the ions do not provide the pressure swings: the electrons do. How and why does that work? What is the speed of the waves? A worksheet will be provided to lead through the steps to derive it, beginning from simple assumptions, arriving at

$$\omega^2 = \frac{C_s^2 k^2}{1 + k^2 \lambda_D^2},$$

where $C_s = \sqrt{T_e/M}$, is the phase velocity of ion acoustic waves in the limit of long wavelengths, also called the ion acoustic speed, $\omega$ and $k$ have their usual meanings, and $\lambda_D$ is called the Debye length.

D. Sketch of procedure: Tone-burst pulse delay Method

Capacitively couple the Agilent function generator (fg) to the Wave Launching Grid. The Langmuir probe will be used as the detector, as shown in figure 3. It to will
FIG. 3. Block diagram of wave set-up.

FIG. 4. Grid and probe are separated by some variable distance; the time delay between the tone burst applied to the grid and the moment of its appearance on the probe can be varied by changing this distance. Note that the directly coupled signal is distorted in a way that the propagating signal is not.

be capacitively coupled to ground so as to make a high pass filter \( (f_c \approx 50kHz) \). The signal across the termination resistor can go to the scope, say Ch.2 (any scope could be used but the Tektronix TDS series scopes have the best digitizers). The output of the osc should go also to the scope, say Ch.1, and this channel should be used to trigger the scope. Choose an excitation frequency well above cutoff frequency and well below the ion plasma frequency. There will always be a direct pick up signal on the probe (a sort of speed of light coupling of the grid signal) but the signal we look for is the one that takes a measurable time to propagate to the probe. The time delay between the received pulse and the sent signal should depend on the speed of those waves in the medium. The time delay should increase as the probe is steadily moved away from the grid. Measure the delay time as function of separation between grid and probe and so determine the speed of the waves. A sample data set for IAWs in ArII is shown in figure 4.

E. Background reading

5. Chapter IV, “Ion Acoustic Waves”, sections 1,2, and 5, p.79-84, 89-97.

7. Ch. 3 [3.1-3.5] in Melissinos.

II. PERSPECTIVES OF THE PLASMA STATE OF MATTER ITSELF

Plasmas are sort of like flames on steroids: seething hot collections of ions, electrons and neutral atoms which exhibit collective effects, or, ‘medium-like behavior’\(^2,3\) For example, in plasmas, terrifically great electric fields arise over a very short distance at material boundaries that keep the electrons in the plasma and push the ions out, just enough to make the net loss of charge zero. The
plasma stays neutral (to a first approximation) and relatively electric field free. This collective effect is called Debye Shielding. The electrostatic potential structure is called the plasma sheath, and is several Debye lengths thick, as shown in fig. 5 below. How the plasma creates the sheath remains a curious problem of research in basic plasma physics, involving self-consistent, nonlinear plasma dynamics.

The energy ions get in the sheath, however, is even greater than that required to form it in the first place. The kinetic energy gained in falling through the sheath potential is used for an enormous variety of plasma processing applications (e.g., ultra large scale integrated circuits, surface modification, and so on). But the kinetic energy in the bulk plasma is useful too. For example, the kinetic energy of the electrons efficiently excites atoms and molecules into high energy states, leading to subsequent spontaneous emission of photons which, directly (in high current gas discharges) and indirectly (in fluorescent tube discharges) provide an important source of lighting. Plasma technology is very practical, and very important to society. Understanding plasma science is therefore very important. Two applications of plasma science are highlighted in figure 6.

Of course, the major thrust of research in the physics of plasmas has to do with realizing fusion energy. Making fusion energy feasible has proved to be a much more difficult problem to solve than was the case for fission energy. Understanding the unexpectedly rich variety of medium-like behaviors of the plasma state of matter has been part of the problem. Solving the (engineering?) problem of shielding a fusion plasma held at 150 million degrees from another superconductor held at a temperature near absolute zero, with only a few centimeters of separation is also part of the problem. It is a challenge that has motivated a couple of generations of bright people to get involved in the work. There will be an enormously great payoff for humanity if the work is ultimately successful: limitless high intensity energy for thousands of years. And yes, that does sound too good to be true, and no, we wouldn’t expect any endeavor with such an enormous payoff to be easy...the claims that should sound not credible are those that offer such a payoff with relative ease. Hold on to your wallet and don’t invest. Fusion? Well, be ready to roll up your sleeves and join the work. It is still a massive undertaking for humanity (well, for the plasma physicists anyway). Fusion is coming!
